I. INTRODUCTION AND PROBLEM STATEMENT

This paper deals with the secrecy guaranteed at the physical layer, namely physical layer security (PLS). The aim is to evaluate the achievable rate on the power delivery infrastructure, or power line communication (PLC) networks, under secrecy constraints. The focus is on the multiple-input, multiple-output and multiple eavesdropper (MIMO-ME) wiretap communication channel, where the transmitter (Alice) wishes to securely transmit a confidential message to the intended receiver (Bob), avoiding any leakage of information to the eavesdropper (Eve), which tries to detect the message.

In order to provide actual and fair results, the intent is to evaluate the performance of the MIMO-ME wiretap channel achieved on real channel measurements and under a realistic background noise assumption. Moreover, the exploitation of all the available wires (phase, neutral and protective earth) with an additional mode, named common mode, together with a different power allocation strategy, provided by an alternating optimization (AO) approach, are discussed and implemented in order to increase the secrecy capacity. Towards this end, also the extended frequency band in the 2–86 MHz is taken into account, as required by the HomePlug AV2 (HPAV2) standard for the next generation devices.

II. PROPOSED SOLUTION OUTLINE

It has already been proved in [1] how the exploitation of the multiple conductor, phase (P), neutral (N) and protective earth (E), at the transmitter and at the receiver side, could noticeably increase the physical layer security of a PLC network. However, the analysis carried out in [1] considers a maximum of 2 spatial transmission and reception modes, a white Gaussian background noise and a 2–28 MHz frequency band. Furthermore, the performance are evaluated relying on a numerically generated network topology based on a bottom up model approach. Otherwise, the purpose of this paper is to consider two Δ -style transmitting modes (P-N and N-E) and four star-style receiving modes (P, N and E) for both the legitimate and hostile nodes, with the additional use of the common mode (CM). It has been proven in [2] as this additional mode, given by the current that flows in the three conductors with the same intensity and direction, could improve performance (without secrecy constraints). This strategy could also result in an improvement of the channel capacity with secrecy constraints, or secrecy capacity.

The performance are evaluated on 353 MIMO channel realizations obtained through an experimental measurement campaign across Europe, collected by the ETSI special task force 410 (STF-410) [3], and considering the 2–86 MHz frequency band extension, according to the latest HPAV2 standard [4]. Furthermore, a colored (with an exponential decreasing profile along frequency) and correlated (between the different receiving modes) Gaussian background noise (for details see [2]), which typically affects real PLC networks, is considered. These assumptions allow to obtain actual and fair results which reflect that of today's and future PLC devices. Moreover, the noise correlation could lead to a performance improvement w.r.t. the same network affected by independent noise (among different modes), with equivalent statistical parameters (mean and variance). This is because the noise correlation could be exploited to aid its cancellation at the receiver side. The “spatial” correlation of the noise (off diagonal elements of the covariance matrix) is modeled according to the procedure discussed in [2].

Last but not least, unlike what has been done in [1] assuming uniform power allocation, the novel approach discussed in [5] to tackle the non-trivial and non-convex secrecy optimization problem in MIMO

wiretap channels, is adopted to compute the “best” power resource allocation at the transmitter side. We choose this strategy since the proposed algorithm is computationally efficient and guarantees the convergence to a Karush-Kuhn-Tucker (KKT) point of the secrecy capacity maximization problem. Even this strategy could lead to an increase of the performance in terms of achievable secrecy capacity.

III. PRELIMINARY NUMERICAL RESULTS AND CONCLUSIONS

We take into account 353 channel measurements performed in the 0–100 MHz frequency band, according to the measurement procedure followed by the STF-410, detailed in [3]. The experimental MIMO channels were divided equally among the legitimate and the unintended receiver ($176 = \lfloor 353/2 \rfloor$ realizations for both the Alice to Bob and Alice to Eve communication channels).

We evaluate the secrecy capacity (shown as C_s) for the $2 \times 4 \times 4$ MIMO-ME wiretap channel for all the channel measurements, under uniform and “best” power allocation strategy (provided by the iterative algorithm discussed in [5]). Two different background Gaussian noise models are considered in Fig. 1, white and independent (on the left side) and colored and correlated (on the right side). As a term of comparison, even the capacity (shown as C) of the MIMO communication channel (without secrecy constraints), with optimal power allocation, is displayed for both the different noise models.

The complementary cumulative distribution function (C-CDF) for the channel capacity and secrecy capacity, achieved with the power allocation provided by the AO algorithm and with uniform allocation (named respectively AO and UN in the picture), are depicted in Fig. 1. It can be noted as the performance without any secrecy constraint (capacity), for the transmission from Alice to Bob, outperforms the secrecy capacity for any power allocation and considered scenario (different background noise), as expected. Furthermore, concerning the secrecy capacity, the use of the alternating optimization (AO) algorithm proposed in [5] (for a power allocation other than uniform), leads to a performance improvement for both the considered background noise models. In fact, it can be seen as the AO approach provides an average secrecy capacity (averaged over the realizations) increase of about 30%, for the white independent noise, and by approximately 20%, for the colored and correlated noise, w.r.t. the uniform power allocation. Obviously, the average channel capacity outperforms the average secrecy capacity (approximately 4 times greater). Finally, note as the secrecy capacity (for both the AO algorithm and uniform allocation), as well as the channel capacity, increases when the network is affected by colored and correlated noise, w.r.t. white and independent noise. This is because, as previously stated, the noise correlation aids its cancellation at the receiver side.
